INFORMATION FROM FIELD DUPLICATES?

PURPOSE: EVALUATE SAMPLING PRECISION

DIFFERENCES BETWEEN SAMPLES REFLECT:

- **Sample collection**
 - Matrix variability
 - Sample container
 - Sample handling
- **Laboratory analysis**
 - Analytical precision
 - Laboratory contamination
 - Instrument carryover

**AIR SAMPLE:
Reusable Container**

**WATER SAMPLE:
Disposable Container**

**KEY
POINT:**

If I do the same thing twice, do I get the same answer?

MOTIVATION FOR THIS STUDY

- Observations and hypothesis formed from personal project experience

Warning: Images not to scale

PROJECT GOALS

- Quantify variability through more rigorous analyses
 - Identify differences in data quality for water vs air samples
 - Identify factors associated with poor data quality

KEY QUESTION: Is duplicate variability greater for vapor samples than for water samples? If so, why?

FIELD DUPLICATE STUDY

STATE WATER RESOURCES CONTROL BOARD
GEOTracker

GeoTracker Database

- Data management system for cleanup sites in California
-
- 65,000+ sites
 - 30,000+ sites w/ electronic data
 - Electronic data from 2001 and after

30,000+ SITES W/ ELECTRONIC DATA

KEY POINT: GeoTracker provides unique resource for data mining.

DATASET

	Vapor
#Sites	400
#Samples	>1,400
Timeframe	2003 - 2016
#Concentration Results	>52,000

KEY POINT: Normal and duplicate results paired up and compared to evaluate variability.

QUANTIFYING DIFFERENCES IN PAIRED DATA

Typical Method: Relative Percent Difference

$$\text{RPD} = \frac{|C1 - C2|}{\text{AVERAGE}(C1, C2)} \times 100\%$$

Alternate Percent Difference (APD)

$$\text{APD} = \frac{|C1 - C2|}{\text{MIN}(C1, C2)} \times 100\%$$

KEY POINT: APD used to better resolve large differences between results.

WHY APD?

Sample Results		Calculations	
Result 1	Result 2	RPD	APD
1	1.3	26%	30%

KEY POINT: Large differences between results approach an RPD of 200%, but get bigger for APD. APD used as basic method to evaluate dataset.

3 RESULTS

4 CONCLUSIONS

DATA PAIRS: GROUPED INTO BUCKETS

DATA PAIR	GROUNDWATER	VAPOR
<i>Both Non-Detect</i>	92% (72,080)	87% (45,433)
<i>One-Detects</i>	1% (599)	3% (1,606)
<i>Two-Detects</i>	7% (5,364)	10% (5,483)

KEY POINT:

Different groups of samples were used to answer different questions.

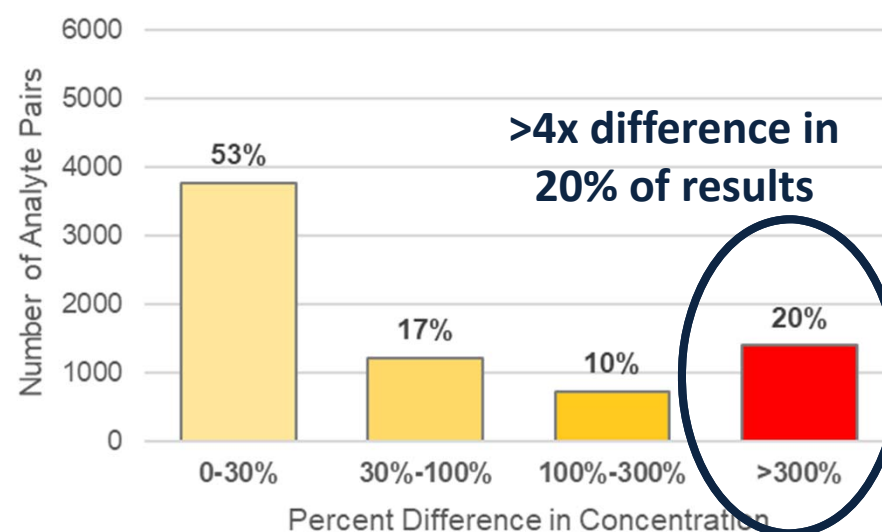

IS THERE A DIFFERENCE BETWEEN GW AND VAPOR PAIRS?

- **YES!**

Water Duplicates

Air Duplicates

KEY POINTS:

- Large differences more common in vapor pairs.
- Initial results confirmed anecdotal observations that vapor samples are more variable than groundwater samples.

DOES CONCENTRATION MATTER?

Not Really

DOES CONCENTRATION MATTER?

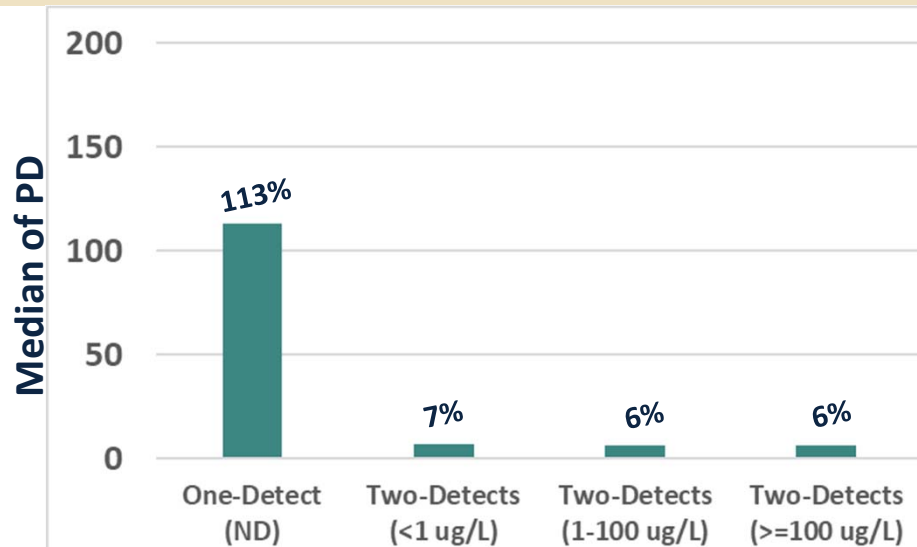

GW: Median of Percent Differences

Vapor: Median of Percent Differences

DOES CONCENTRATION MATTER?

GW: Median of Percent Differences

Vapor: Median of Percent Differences

KEY POINT:

- Good analytical precision across concentration ranges.
- Duplicate variability was higher for one-detect analyte pairs.
- Implies difference not due to analytical precision.

Note: Evaluation of one- and two-detects, grouped into concentration range buckets by the lowest value in the pair. Detection limit substituted for non-detect results.

HIGH VARIABILITY IN ONE-DETECT PAIRS

- Apparently caused by “sample contamination”
 - Sampling process, container, sample prep in lab, carry-over contamination during analysis
- Seen for GW and vapor, but worse for vapor

	GROUNDWATER	VAPOR
Median PD	113%	665%
How Common are 1-D Pairs?	10% of pairs	23% of pairs
Container		

KEY POINT: Sample contamination issues are more significant for vapor samples than for water samples. One key difference: re-use of containers for vapor.

WHAT IS THE IMPACT OF “SAMPLE CONTAMINATION?”

DATA EVALUATION ASSUMPTIONS:

PAIR TYPE

MOST LIKELY EXPLANATION

Two-Detects

- Chemical IS present at sample point

Both Non-Detects

- Chemical NOT present at sample point

One-Detects

- Chemical NOT present at sample point
- One “False Positive” in the sample pair due to sample contamination introduced during collection or analysis

WHAT IS THE IMPACT OF “SAMPLE CONTAMINATION?”

ESTIMATION OF SAMPLE CONTAMINATION RATE:

$$\text{Contamination Rate} = \frac{\text{Number of “False Positive” Results}}{\text{Number of Pairs where Chemical Not Present in Sample Point}} \times 100\%$$

$$\text{i.e., Contamination Rate} = \frac{\text{No. of One-Detect Pairs} \times 0.5}{(\text{No. of Zero-Detect Pairs} + \text{No. of One-Detect Pairs})} \times 100\%$$

KEY POINT: Equation estimates percentage of “false positive” detections for individual analytes.

PERCENT “CLEAN” SAMPLES AFFECTED BY SAMPLE CONTAMINATION

Groundwater

Acetone
(common lab contaminant)

Vapor

Acetone
(common lab contaminant)

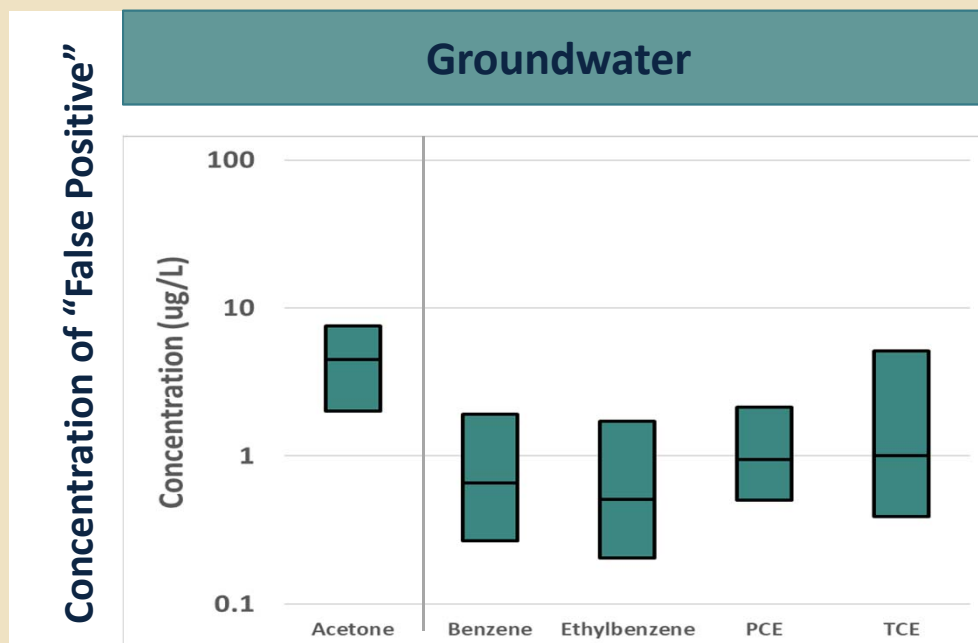

KEY POINT:

For GW, contamination rate < 2% for all individual analytes.
For vapor, acetone 12%; common site contaminants 4-6%.

Note: Evaluation of zero- and one-detect pairs.

DOES SAMPLE CONTAMINATION MATTER?

LEGEND

KEY POINT: For site contaminants, median GW concentrations are about 1 $\mu\text{g/L}$.

DOES SAMPLE CONTAMINATION MATTER?

KEY POINT:

In most cases, the "False Positive" GW concentration is less than typical groundwater screening levels (e.g., MCLs).

SOIL GAS VS. INDOOR/OUTDOOR?

LEGEND

Interquartile Range

75th percentile

median

25th percentile

Concentration of "False Positive"

Soil Gas

Acetone
(common lab contaminant)

Indoor/Outdoor Air

Acetone
(common lab contaminant)

KEY POINT: For site contaminants, concentrations in affected soil gas samples about 10x higher than air samples.

SOIL GAS VS. INDOOR/OUTDOOR?

LEGEND

Concentration of “False Positive”

KEY POINT: “False Positive” concentrations generally less than screening levels for soil gas (except TCE). More problematic for indoor air.

Note: Soil Gas SLs from USEPA VISL; residential Indoor Air Screening Levels per USEPA, Nov 2017 RSL table (TR=1e-6; THQ=1).

IMPLICATIONS: *SOIL GAS VS. AIR*

- Concentration of acetone similar between soil gas and air.

➔ Non-site sources of sample contamination important.

- Soil gas commonly contains higher VOC concentrations than air.

➔ Sample contamination and carryover is a larger concern.

- “False Positive” conc. of common site contaminants approx. 10x higher for soil gas compared to air.

➔ Source likely incomplete cleaning of reusable sample containers (Summa canisters).

KEY POINT:

Because indoor air screening values are so low, false positive detections of site chemicals will likely lead to additional investigation, response actions.

4 CONCLUSIONS

Warning: Images not to scale

CONCLUSIONS

Vapor Duplicate Pairs

- Sample contamination causes detectable concentrations in 4-6% of “clean” samples (i.e., samples that would normally yield non-detect results).
- This “False Positive” rate is for *individual chemicals* (not for the false detection of any chemical in a *sample*. The sample false positive rate would be higher.)
- “False Positive” detections are likely to be above indoor air screening values.

KEY POINT: Majority (>90%) of results were not impacted by sample contamination. However, the possibility of sample contamination should be considered in cases of unexpected results.

RECOMMENDATIONS

Data Interpretation:

Consider Sample Contamination when:

- Analyte is detected in small percentage of site samples. No clear pattern to detections.
- Detected analyte not otherwise expected to be a site contaminant (e.g., chlorinated solvent at petroleum release site).

*Project Planning**:*

- Does laboratory segregate soil gas from air canisters?
- Batch vs. individually certified-clean canisters
- Clean to detection limit, reporting limit, other limit?

KEY POINT: Don't make big decisions based on one or two detections in a sampling program.

** Note: Our study did not evaluate whether any of these measures actually reduce the “false positive” rate.
